

# A Randomized, Double-Blind, Placebo-Controlled Trial of Niacinamide for Reduction of Phosphorus in Hemodialysis Patients

Steven C. Cheng, Daniel O. Young, Yihung Huang, James A. Delmez, and Daniel W. Coyne

*Division of Nephrology, Washington University School of Medicine, St. Louis, Missouri*

**Background and objectives:** Niacinamide inhibits intestinal sodium/phosphorus transporters and reduces serum phosphorus in open-label studies. A prospective, randomized, double-blind, placebo-controlled crossover trial was performed for assessment of the safety and efficacy of niacinamide.

**Design, setting, participants, & measurements:** Hemodialysis patients with phosphorus levels  $\geq 5.0$  mg/dl were randomly assigned to 8 wk of niacinamide or placebo, titrated from 500 to 1500 mg/d. After a 2-wk washout period, patients switched to 8 wk of the alternative therapy. Vitamin D analogs and calcimimetics were held constant; phosphorus binders were not changed unless safety criteria were met.

**Results:** Thirty-three patients successfully completed the trial. Serum phosphorus fell significantly from 6.26 to 5.47 mg/dl with niacinamide but not with placebo (5.85 to 5.98 mg/dl). A concurrent fall in calcium-phosphorus product was seen with niacinamide, whereas serum calcium, intact parathyroid hormone, uric acid, platelet, triglyceride, LDL, and total cholesterol levels remained stable in both arms. Serum HDL levels rose with niacinamide (50 to 61 mg/dl but not with placebo. Adverse effects were similar between both groups. Among patients who were  $\geq 80\%$  compliant, results were similar, although the decrease in serum phosphorus with niacinamide was more pronounced (6.45 to 5.28 mg/dl) and the increase in HDL approached significance (49 to 58 mg/dl).

**Conclusions:** In hemodialysis patients, niacinamide effectively reduces serum phosphorus when co-administered with binders and results in a potentially advantageous increase in HDL cholesterol. Further study in larger randomized trials and other chronic kidney disease populations is indicated.

*Clin J Am Soc Nephrol* 3: 1131–1138, 2008. doi: 10.2215/CJN.04211007

Elevated serum phosphorus contributes to the development of secondary hyperparathyroidism and renal osteodystrophy. In dialysis patients, hyperphosphatemia can lead to metastatic calcifications and is associated with increased cardiovascular mortality (1,2). The majority of dialysis patients require dietary phosphorus restrictions and phosphate binders to control serum phosphorus. Despite these measures, most patients fail to achieve predialysis serum phosphorus levels  $< 5.5$  mg/dl (2,3).

Niacinamide (also known as nicotinamide) and niacin are the principle forms of vitamin B<sub>3</sub>. Despite structural similarities and equivalent nutritional properties, niacinamide and niacin have differing actions and adverse effect profiles. Although niacinamide can cause gastrointestinal discomfort and reportedly lowers platelet counts, it does not cause flushing, which is commonly seen with niacin (4,5). *In vitro* studies have shown that niacinamide decreases phosphate uptake by inhibiting so-

dium/phosphorus co-transporters in the renal proximal tubule (Na/Pi2a) and intestine (Na/Pi2b) (6–9). An open-label study of niacinamide in Japanese hemodialysis patients who were not taking phosphorus binders found that dosages up to 1750 mg/d decreased serum phosphorus from 6.9 to 5.4 mg/dl (10). In addition, HDL cholesterol increased and LDL cholesterol declined during the 12 wk of treatment.

Dialysis patients in the United States have poorer phosphorus control and might benefit from the addition of niacinamide to their binder regimen. To evaluate further the effect of oral niacinamide in hemodialysis patients, we performed a prospective, randomized, double-blind, placebo-controlled, crossover study of hyperphosphatemic hemodialysis patients. For assessment of the additive effects of niacinamide to binder therapy, patients were maintained on their binder regimen throughout the study unless safety criteria for dosage titration were met.

## Materials and Methods

### Enrollment

This study was approved by the Human Studies Committee at Washington University School of Medicine and registered in a clinical trials database (NCT00316472, <http://www.clintrials.gov>). Patients were recruited at two urban dialysis units operated by Washington University School of Medicine, Division of Nephrology, from February 2006

Received October 5, 2007. Accepted March 5, 2008.

Published online ahead of print. Publication date available at [www.cjasn.org](http://www.cjasn.org).

through December 2006. Inclusion criteria were (1) age >18 yr, (2) capacity for informed consent, (3) on long-term hemodialysis >90 d, (4) stable dosage of phosphorus binder(s) during the previous 2-wk period, and (5) serum phosphorus level  $\geq 5.0$  mg/dl on the most recent monthly laboratory data. The criteria of a serum phosphorus  $\geq 5.0$  mg/dl was used to enroll patients who were within the acceptable range of the current Kidney Disease Outcomes Quality Initiative (KDOQI) recommendations (serum phosphorus <5.5 mg/dl) but still above the goal of normalizing serum phosphorus levels. Patients were excluded for any of the following criteria: Pregnancy, history of liver disease, active peptic ulcer disease, treatment with carbamazepine, on niacin therapy, more than one missed hemodialysis session in the past 30 d, planned or expected surgical procedure in the ensuing 4 mo, or residency at a nursing home or extended care facility where administration of the study drug may not be appropriately given.

For exclusion of patients with isolated elevations in serum phosphorus, a 2-wk screening phase followed consent. Serum phosphorus was measured before the first dialysis of both weeks. Patients were randomly assigned when the average screening phosphorus was  $\geq 5.0$  mg/dl.

**Study Medication and Randomization**

Niacinamide powder was purchased from Spectrum Chemical Manufacturing Corporation (New Brunswick, NJ). Identical capsules containing 250 mg of niacinamide or placebo were manufactured by a research pharmacist (Stephanie Porto, RPharm, Barnes-Jewish Hospital, St. Louis, MO). The research pharmacist also randomly assigned patients and provided blinded bottles to the research staff for distribution. Bottles contained sufficient capsules for the next 2 wk on the basis of the patient’s randomization order.

**Study Design**

The study was a crossover design (Figure 1). After successful screening, patients were randomly assigned to either placebo or niacinamide. After 8 wk with forced dosage titration (described in the next section), there was a 2-wk washout period, then 8 wk on the alternative therapy. Serum calcium and phosphorus levels were measured weekly. Serum albumin, intact parathyroid hormone (iPTH), uric acid, and complete blood count were obtained at weeks 1, 9, 11, and 19. Additional complete blood counts were drawn weeks 5 and 15 to monitor for thrombocytopenia. Lipid panels were drawn at weeks 1, 9, and 19. All laboratory values were drawn before dialysis on the first dialysis

Figure 1. After a 2-wk screening phase, patients were randomly assigned to 8 wk of niacinamide or placebo with titration from 250 to 750 mg twice daily. A 2-wk washout preceded the switch from niacinamide to placebo or vice versa.

treatment of each week. Phosphorus binders, vitamin D, paricalcitol, and cinacalcet were continued at the same dosage throughout the study unless changes were necessary for patient safety.

**Dosage Titration**

Niacinamide or placebo was administered at a starting dosage of one capsule (250 mg) twice daily. The dosage was increased to 500 mg (two capsules) twice daily at week 3 and 750 mg (three capsules) twice daily at week 5. When hypophosphatemia (<3.5 mg/dl) was present, the previous dosage was continued. Titration resumed once the serum phosphorus rose above 3.5 mg/dl. When consecutive serum phosphorus levels were <3.0 mg/dl, study drug was decreased by two capsules per day. Study drug dosage could also be decreased if patients had adverse effects attributable to the study drug. The same dosage titration occurred after washout, beginning in week 11. Pill counts were performed at each dosage titration and at the completion of each study arm.

**Safety Stop Points**

A decrease in phosphorus binders was permitted when serum phosphorus remained <3.0 mg/dl despite a decrease in the dosage of study drug. An increase in binders, in conjunction with dietary counseling, was permitted when two consecutive phosphorus levels were >7.0 mg/dl or the calcium-phosphorus product was >70 mg<sup>2</sup>/dl<sup>2</sup>. When phosphorus binder dosage was changed during the first arm of the study, the new regimen was continued through the remainder of the study.

**Statistical Analyses**

Statistical analysis was performed using two-sample paired-group *t* test. The primary end point was the change in serum phosphorus from the first to the last week of each arm. Predefined secondary end points were the change in iPTH, calcium, calcium-phosphorus products, uric acid, platelets, and lipid profile parameters (HDL, LDL, triglycerides). An *a priori* power analysis, assuming an expected phosphorus difference of 1.0 mg/dl with an expected SD of 1.0 mg/dl, showed that 24 patients were needed to achieve 90% power at the 5% significance level. For accounting for dropout and noncompliance, planned recruitment was 40 patients. Upon completion of the study, primary and secondary end points were evaluated for all patients, then repeated among compliant patients, defined by  $\geq 80\%$  use of study pills during each arm.

**Data Reporting**

The results of this randomized, controlled trial are reported in compliance with the guidelines established by the CONSORT statement (11).

**Results**

**Patient Population**

A total of 42 patients underwent screening, and 33 were randomly assigned into the trial. All 33 completed the 20-wk study, and 25 of 33 were  $\geq 80\%$  compliant with medications by pill counts (Figure 2). Patient characteristics are shown in Table 1, and baseline data are displayed in Table 2. Laboratory results at the start and completion of placebo and niacinamide arms are summarized in Table 3.

**Dosing Characteristics**

In accordance with our protocol, the dosages of vitamin D analogs and calcimimetics were not changed for any patient

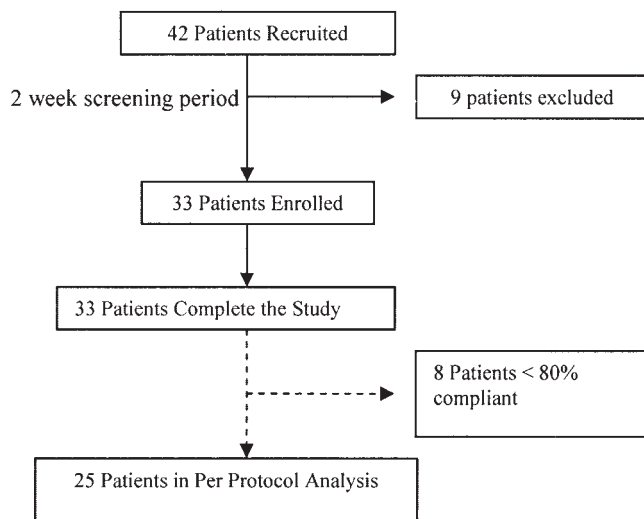

Figure 2. After the 2-wk screening period, 33 patients were enrolled in the study. All patients completed the study; 25 demonstrated compliance with the study regimen and were included in the per-protocol analysis.

during the study. All patients on vitamin D analogs were treated with paricalcitol. Three patients had a change in phosphorus binders required by our safety stop points. Binders were increased for one patient during placebo (lanthanum carbonate 1000 mg three times daily to 1500 mg three times daily) and one patient during niacinamide (calcium acetate 1334 mg three times daily to 2001 mg three times daily). One patient required a decrease in binder at week 5 of the niacinamide arm (sevelamer 2400 mg three times daily to 1600 mg three times

Table 1. Patient characteristics ( $N = 33$ )

Characteristics	% (n)	Average Dosage

Binder regimen		
sevelamer hydrochloride	76 (25)	7624 mg/d
lanthanum carbonate	12 (4)	3000 mg/d
calcium carbonate	18 (6)	1775 mg/d
calcium acetate	27 (9)	5225 mg/d

daily). Mean dosages of paricalcitol, calcimimetics, and phosphorus binders are contained in Table 1.

Changes in dialysis prescription were permitted to achieve targets for dialysis adequacy as reflected by monthly KT/V. Among the 31 patients on thrice-weekly hemodialysis, there was no significant difference between KT/V during placebo and niacinamide (1.60 versus 1.56, respectively;  $P = 0.44$ ). The two patients on hemodialysis four times per week had an average KT/V of 1.1 during placebo and 1.06 during niacinamide, also NS ( $P = 0.89$ ).

#### Serum Phosphorus

Among all patients, treatment with placebo resulted in an insignificant rise in serum phosphorus from 5.85 to 5.98 mg/dl ( $P = 0.73$ ). Treatment with niacinamide resulted in a significant fall in serum phosphorus from 6.26 to 5.47 mg/dl ( $P = 0.02$ ). The change in serum phosphorus was significantly different between the two groups: The mean change on placebo was +0.13 mg/dl (95% confidence interval [CI]  $-0.53$  to  $0.79$  mg/dl), whereas the mean change on niacinamide was  $-0.79$  mg/dl (95% CI  $-0.12$  to  $-1.46$  mg/dl;  $P = 0.05$ ; Figure 3). The largest change in serum phosphorus occurred during the first 2 wk on niacinamide, at a dosage of 250 mg twice daily. Phosphorus levels fell from 6.26 to 5.76 mg/dl during this period but did not reach statistical significance ( $P = 0.14$ ). Dosage titration to the maximum of 750 mg twice daily further reduced serum phosphorus, with levels falling from 5.9 to 5.47 mg/dl during the final 4 wk of the active arm.

#### Secondary End Points

The calcium-phosphorus product decreased significantly (59 to 52  $\text{mg}^2/\text{dl}^2$ ;  $P = 0.03$ ) with niacinamide while increasing insignificantly during placebo treatment (54 to 57  $\text{mg}^2/\text{dl}^2$ ;  $P = 0.52$ ). There were no significant changes in serum calcium during either treatment arm. Calcium, iPTH, and uric acid levels did not change in either arm, and there were no significant differences in total cholesterol, triglycerides, or LDL cholesterol between arms. HDL cholesterol rose from 50 to 61 mg/dl ( $P = 0.035$ ) on niacinamide while remaining unchanged on placebo (Figure 4).

Thrombocytopenia has been reported as an adverse effect of niacinamide (4). In our study, the platelet count tended to rise on placebo and fall on niacinamide (+9000 on placebo versus  $-17,000/\text{mm}^3$  on niacinamide;  $P = 0.07$ ). Although no patients developed bleeding complications during the study, nine had thrombocytopenia (platelet count  $<150,000/\text{mm}^3$ ) with niacinamide and five had thrombocytopenia on placebo. A platelet count of  $<100,000/\text{mm}^3$  was seen in one patient on niacinamide and two patients on placebo. The trend in platelet counts among patients with thrombocytopenia on niacinamide is shown in Table 4.

#### Adverse Effects

Two patients complained of diarrhea while receiving niacinamide, one of whom had diarrhea before use of the study drug. This patient had spontaneous resolution of his symptoms without a reduction in dosage. The other had a dosage reduction from 750

Table 2. Baseline data

Parameter	Week 1 Placebo	Week 1 Niacinamide	P
Age (yr)	52.6	52.6

<sup>a</sup>Values changed significantly.

to 500 mg twice daily with subsequent symptomatic improvement. No diarrhea was reported during placebo therapy. One patient complained of a rash on his abdomen during week 8 of niacinamide, which resolved after 4 d. There were no reports of flushing.

During the course of the study, eight patients were admitted to the hospital. Four were admitted during the placebo arm with diagnoses of osteoarthritis, septic arthritis, and volume overload (two patients). On niacinamide, three patients were admitted with diagnoses of volume overload, a nonhealing foot ulcer, and osteomyelitis. The last patient was excluded in the per-protocol analysis. One patient developed pneumonia during the washout period. There were no deaths.

#### Per-Protocol Analysis

A total of 25 of the 33 patients were ≥80% compliant with the study on the basis of pill counts and were assessed in the per-protocol analysis. The results parallel the findings described among the total study population (Table 5). Serum phosphorus rose insignificantly (from 5.59 to 5.96 mg/dl; *P* = 0.40) on placebo but decreased significantly from 6.45 to 5.28

Figure 3. Serum phosphorus levels rose during the 8 wk of the placebo arm (solid line) but decreased significantly during treatment with niacinamide (dotted line). Placebo *n* = 33; niacinamide *n* = 33.

Figure 4. Effect of niacinamide on HDL cholesterol levels is shown in both randomization schemes. Among all patients, HDL cholesterol levels increased significantly on niacinamide (50 to 61 mg/dl;  $P = 0.035$ ). Placebo  $n = 33$ ; niacinamide  $n = 33$ .

mg/dl ( $P = 0.002$ ) with niacinamide. There was a statistically significant difference between the mean change in serum phosphorus on placebo (+0.37 mg/dl; 95% CI -0.37 to 1.11 mg/dl) and the mean change on niacinamide (-1.17 mg/dl; 95% CI -0.52 to -1.82 mg/dl;  $P = 0.002$ ; Figure 5). As expected, there was a concomitant fall in the calcium phosphorus product with niacinamide, from 61 to 51 mg<sup>2</sup>/dl<sup>2</sup> ( $P = 0.003$ ); serum calcium remained stable. Neither serum calcium nor calcium-phosphorus product changed significantly during placebo therapy. iPTH and uric acid levels remained the same in both arms. The compliant subset showed no change in total cholesterol, triglycerides, or LDL during either arm, but HDL levels after treatment with niacinamide approached significance (49 to 58 mg/dl;  $P = 0.07$ ) while remaining unchanged in the placebo arm. During the 8-wk study period, the platelet

count in the compliant subset fell from 214,000 to 197,000 ( $P = 0.10$ ) during niacinamide. Among patients with thrombocytopenia described in Table 4, only patients 2 and 8 were <80% compliant with the study regimen.

### Discussion

The two major forms of vitamin B<sub>3</sub> are niacin (or nicotinic acid) and its amide, niacinamide, also known as nicotinamide. Because niacinamide serves as a central component of nicotinamide adenine dinucleotide and nicotinamide adenine dinucleotide phosphate, it plays an important role in sustaining several crucial metabolic processes. As such, supplementation may be useful over a broad range of metabolic disorders. In the clinical setting, niacinamide is used primarily for the treatment of acne and pellagra; however, niacinamide has also been studied in insulin-dependent diabetes, where it may preserve pancreatic  $\beta$  cells (12), and ischemia-reperfusion injury, where it inhibits nitric oxide synthase (13). Niacinamide may mediate a variety of protective mechanisms through downregulation of TNF- $\alpha$  (14), increased free radical scavenging (15), and inhibition of poly-ADP-ribose synthetase, an emerging target for cardiovascular disease and cancer (16). Niacinamide is now known to inhibit sodium/phosphorous transport in both renal and intestinal brush borders, stimulating interest in its use for phosphorus reduction among patients with chronic kidney disease.

In large, multicenter studies, elevated serum phosphorus has been associated with an increase in morbidity and mortality in patients with ESRD (1,17,18). Hyperphosphatemia is linked to cardiovascular risk as well as bone disease (19,20), and the hyperphosphatemic milieu may promote vascular calcification through cellular changes in vascular smooth muscle cells (21). Previous open-label studies by Takahashi *et al.* (10) and Sampathkumar *et al.* (22) demonstrated that niacinamide lowers serum phosphorus levels in maintenance hemodialysis patients when traditional binding agents are withheld. This study is the first randomized, double-blind, placebo-controlled study to assess the effectiveness of niacinamide on phosphorus reduction in conjunction with phosphorus binders.

Table 4. Platelet counts in patients with thrombocytopenia during niacinamide<sup>a</sup>

Patient	Niacinamide Arm			Follow-up
	Week 1	Week 5	Week 9	
1	145 <sup>b</sup>	297	267	Completed study

Figure 5. Serum phosphorus is represented by the solid line during the placebo arm and the dotted line during niacinamide. Among compliant patients, a more pronounced difference was noted in the change in serum phosphorus between placebo and niacinamide (+0.37 on placebo versus  $-1.17$  mg/dl on niacinamide;  $P = 0.002$ ). Placebo  $n = 25$ ; niacinamide  $n = 25$ .

After 8 wk of therapy, patients in our study had a statistically and clinically significant drop in serum phosphorus and calcium-phosphorus product, whereas serum calcium and uric acid levels remained unchanged. The reduction in serum phosphorus and calcium-phosphorus product was more pronounced in the compliant subgroup analysis. The fall in phosphorus was most notable during the initial 2-wk period, which was associated with highest serum phosphorus levels and the lowest dosage (250 mg twice daily) of niacinamide; however, levels continued to decrease through the titration to 750 mg twice daily. Phosphorus levels may have continued to fall without titration to higher dosages, and further studies comparing different dosages for longer time periods are needed to address this issue.

The effect of niacinamide on HDL levels was somewhat surprising. Although niacin is known to increase serum HDL, previous reports suggested that in normal and hyperlipidemic individuals, niacinamide does not have similar effects on lipid metabolism (23,24). Although a detailed mechanism for their distinctive actions has yet to be understood, a nicotinic acid (niacin) receptor that binds niacin but not the nutritionally equivalent amide form, niacinamide, has been characterized (25,26). The effects of these compounds in uremic individuals is even less well studied; however, Takahashi *et al.* (10) reported that niacinamide raised HDL from 47 to 67 mg/dl ( $P < 0.0001$ ) and lowered LDL from 79 to 70 mg/dl ( $P < 0.01$ ) in Japanese patients on hemodialysis. Our study demonstrated an increase in HDL of 11 mg/dl (a 21.5% increase) with niacinamide, although no LDL-lowering effect was seen. The kinetics of the HDL changes could not be characterized because lipid panels were drawn only at the start and completion of the treatment arms. Of note, most patients in our study were concomitantly treated with sevelamer, which lowers LDL *via* bile acid binding (27,28). This may obscure further lipid lowering by niacinamide. The cumulative effect of niacinamide on lipid metabolism observed in our study may have important benefits in chronic kidney disease and dialysis patients and warrants further investigation.

Niacinamide seems to be well tolerated in the general population (29). Even at our maximum daily dosage of 1500 mg, there were no major adverse effects. Only one patient (of 33) required a dosage adjustment because of diarrhea, which resolved when niacinamide was decreased from 1500 to 1000 mg/d. This is in marked contrast to a report by Delanaye *et al.* (5) that noted the occurrence of diarrhea in five of six patients enrolled in an open-label trial of the safety and efficacy of niacinamide. The symptoms from that report began at a mean niacinamide dosage of  $1050 \pm 447$  mg and resolved after drug cessation. Patients in that study were on calcium-based and/or sevelamer-based binder regimens. The authors speculated that co-administration of phosphorus binders with niacinamide may have contributed to the severe diarrhea, because a much lower percentage of patients (7.8%) in Takahashi's cohort de-

veloped diarrhea when niacinamide was administered alone (10). In our study, 76% were on concurrent sevelamer hydrochloride, 12% were on lanthanum carbonate, and 45% were on calcium-based binders, and only 6% (two of 33) of the total study population and 8% (two of 25) of the compliant subset complained of diarrhea. No patients were removed from the study, and there were no deaths during the study period. Hospitalizations were roughly equivalent between the two groups, with all admissions related to underlying comorbidities and not the administration of niacinamide. Hospitalization may also transiently affect serum phosphorus levels and confound results; however, when hospitalized patients are removed from the per-protocol analysis, a significant change in phosphorus during niacinamide treatment is still noted (6.6 to 5.2 mg/dl;  $P < 0.05$ ), whereas phosphorus remains unchanged during placebo.

Thrombocytopenia has been a concern from previous studies of niacinamide, and our analysis did find a trend toward decreasing platelet counts on niacinamide. Nevertheless, no clinical manifestations of thrombocytopenia complicated the administration of study drug in our study. The mechanism by which niacinamide may decrease platelet counts is not fully understood. Studies with nicotinic acid suggested that thrombocytopenia may be mediated through a decrease in thyroxin-binding globulin (4). Although clinical manifestations did not occur during our study period, further investigation is warranted to evaluate the effect of niacinamide on platelets for a longer period of administration. For now, monitoring for thrombocytopenia in dialysis patients on niacinamide is prudent.

This study supports the usefulness of niacinamide in hemodialysis patients with hyperphosphatemia. Furthermore, it seems to be well tolerated, and its effect on serum HDL levels is particularly appealing for a population at high risk for cardiovascular disease. As demonstrated here, niacinamide can be used in conjunction with phosphorus binders, although it does not need to be administered with meals. A recent study found that niaspan (prolonged-release niacin) also reduced phosphorus and raised HDL levels in dialysis patients after washout from calcium-based binders (30). Although both forms of vitamin B<sub>3</sub> have now shown favorable effects on lipid and phosphorus levels, they are clinically distinguished by distinct differences in adverse effects. Flushing remains an important limitation to the titration of niacin in some patients, whereas further studies are needed to evaluate niacinamide's effect on platelet counts.

## Conclusions

This randomized, double-blind, placebo-controlled, crossover trial demonstrates that niacinamide is effective in controlling serum phosphorus when co-administered with phosphorus binders in patients on hemodialysis. Moreover, niacinamide increased serum HDL levels. The combination of phosphorus reduction with a beneficial change in lipid profiles makes niacinamide an attractive agent for further investigation and use for patients who are on maintenance hemodialysis.

## Acknowledgments

D.O.Y. received support for this study through the Amgen Fellowship Support Stipend during the 2006 to 2007 academic year.

## Disclosures

None.
