Background and objectives: Urine microscopy is the oldest and one of the most commonly used tests for differential diagnosis of acute kidney injury (AKI), but its performance has not been adequately studied in the setting of AKI.

Design, setting, participants, & measurements: Fresh urine samples were obtained from 267 consecutive patients with AKI, and urinary sediment was examined. The cause of AKI was assessed at two time points: (1) Before urine microscopy diagnosis and (2) after patient discharge or death (final diagnosis). A urinary scoring system also was created on the basis of casts and renal tubular epithelial cells (RTEC) to differentiate acute tubular necrosis (ATN) from prerenal AKI.

Results: The urinary sediment scoring system was highly predictive of the final diagnosis of ATN. In patients with a high pretest probability of ATN (initial diagnosis of ATN), any casts or RTEC (score ≥2) resulted in very high positive predictive value and low negative predictive value for a final diagnosis of ATN. In patients with a low pretest probability of ATN (initial diagnosis of prerenal AKI), lack of casts or RTEC on urinary sediment examination had a sensitivity of 0.73 and specificity of 0.75 for a final diagnosis of prerenal AKI. The negative predictive value of lack of casts or RTEC in patients with low pretest probability of disease was 91%.

Conclusions: Urine sediment examination is a valuable diagnostic tool for confirming the diagnosis of ATN. A score of ≥2 on an ATN urinary sediment scoring system is an extremely strong predictor of ATN.

Urine microscopy is the oldest and one of the most commonly used tests for differential diagnosis of acute kidney injury (AKI). The diagnosis of AKI is currently and primarily based on measurement of serum creatinine, blood urea nitrogen, and urine output. In addition to these parameters, urine biochemistry and microscopy provide the vital information in the differentiation of AKI into traditional categories of prerenal azotemia and acute tubular necrosis (ATN) (1–5). Therapies and prognosis for prerenal AKI and ATN differ substantially; therefore, early clinical differentiation is important. Although urine microscopy with sediment examination is commonly suggested for patients with AKI in the literature, its precise diagnostic value is not clearly known. Furthermore, there has been a gradual trend away from routine urine microscopy in the clinical evaluation of AKI.

Urinary microscopy in patients with ATN classically is described as containing renal tubular epithelial cells (RTEC), RTEC casts, granular casts, and muddy brown or mixed cellular casts, whereas sediment in patients with prerenal AKI usually demonstrates occasional hyaline or fine granular casts (6–10). Because urine microscopy is readily available, rapid, and inexpensive, valuable information that will improve the differential diagnosis of AKI might be quickly obtained from this test. The aims of this study were to describe the urinary sediment findings in a cohort of patients with AKI and to determine the performance of urinary sediment examination for differentiation between ATN and prerenal AKI, the most common causes of AKI in the hospital.

Materials and Methods

In this cross-sectional study, fresh urine samples were obtained from 267 consecutive patients who were seen for diagnosis of AKI by the nephrology consult service at Yale New Haven Hospital between April 2006 and May 2007. AKI was defined as a 50% increase in serum creatinine concentration above baseline. In reality, most patients had much more severe increases in serum creatinine concentration at the time of nephrology consultation. The consultant nephrologist was asked to assess the probable cause of AKI at two time points: (1) After clinical assessment of the patient but before urine microscopy (preurine microscopy diagnosis) and (2) after patient discharge, renal biopsy, or death (final diagnosis). These findings were recorded on a data collection form provided to all consultants on the nephrology service and maintained in a secure location. Before the study, all physicians who participated were instructed by senior faculty from the Section of Nephrology at Yale on the evaluation of the urine sediment to ensure that all readers were competent to identify adequately the cellular elements and various cast forms. Instruction included both didactic education about the various cellular elements and casts found in the urine, which included proper collection, preparation, and viewing of the urine. In addition, hands-on demonstration of proper urine preparation and visualization of fresh urine samples from patients with

various forms of kidney disease (prerenal AKI, ATN, glomerulonephritis, vasculitis, acute interstitial nephritis, urinary infection, and obstructive nephropathy) was undertaken. Instruction on proper use of the bright-field microscope with polarization (for crystals) was undertaken.

At the first time point, the consultants were asked to provide a diagnosis of AKI that fit into one of three categories: ATN, prerenal AKI, or other. The term ATN was used to reflect sustained AKI that did not fit into other categories of intrinsic renal disease. The consultants were instructed to use all available clinical data to make these presumptive diagnoses, including clinical scenario, temporal course of serum creatinine concentration, and response to treatment (including intravenous fluids, discontinuation of or addition of diuretics, vasopressors, and use of steroids). As a general guideline, ATN, although truly a biopsy diagnosis, was defined as a sudden decline in kidney function as manifested by a 50% increase in serum creatinine concentration above baseline that did not respond to fluid resuscitation and/or hemodynamic manipulation (e.g., vasopressors) within 48 h of treatment. Prerenal AKI was defined as an abrupt decline in baseline kidney function (as already defined) that improved to ≤10% of baseline after fluid resuscitation and/or hemodynamic manipulation within 48 h. The third category was labeled as “other” and included diagnoses such as glomerulonephritis, vasculitis, pyelonephritis, preeclampsia, interstitial nephritis, and obstructive nephropathy.

After the initial consultation, fresh urine was obtained from the patients and were examined within 1 h after voiding. The consultant nephrologists prepared urine sediment samples for analysis. Ten milliliters of urine was centrifuged at 1500 rpm for 5 min in a standard centrifuge (inspected and maintained by Yale-New Haven Hospital). Removal by suction of 9.5 milliliters of supernatant urine was performed and followed by gentle manual agitation of the test tubes. A pipette was used to apply a single drop of urine sediment on a glass slide, and coverslip was gently applied. There was no variation in types of glass slides or coverslips used during the study. Samples were examined at low power (×10) and then at high power (×40) on the bright-field microscope. The urine was also viewed with polarization when crystals were identified. Urinary sediment was analyzed for the presence and number of red and white blood cells, RTEC, granular casts, and hyaline casts (all per high-power field). RTEC are defined as size variation (11 to 15 μm in diameter), shape variation (round to columnar), and a well-evident nucleus with nucleoli. Granular casts are defined as fine or coarse granules contained within a cast matrix, whereas hyaline casts are defined as cast matrix without cells and colorless. Granular casts and RTEC per high-power field were recorded on the data collection sheet as present or absent and, when present, were also quantified as the number counted: one to five, six to 10, and >10 and one to five, six to 20, >20, respectively. Other casts, such as hyaline, red blood cell, and white blood cell casts per high-power field, were also recorded. Urine sediments were verified by two physicians.

Finally, the diagnosis of AKI was assessed at the second time point (approximately 1 to 4 wk after the initial consultation). The consultants were asked to include all of the available clinical information (especially response to therapy over time and renal biopsy diagnosis) and record the “final diagnosis” of AKI for the individual patients.

For the statistical analyses, we included only patients with ATN and prerenal AKI according to the final diagnosis. We assessed the sensitivity, specificity, positive predictive value (PPV; true positives/true positives + false positives), negative predictive value (NPV; true negatives/true negatives + false negatives) of both the initial diagnosis for the final diagnosis and of granular casts for the diagnosis of ATN. We also created a scoring system based on casts and RTEC and evaluated its accuracy for differentiating ATN from prerenal AKI (Table 1). Likelihood ratios (LR) were calculated for a diagnosis of both ATN and prerenal AKI using data from the urine sediment scoring system. The protocol was approved by the human investigation committee at Yale University.

Results

Nine consultants participated in the study and primarily examined the urine sediment or verified findings. In our cohort, 125 (47%) patients had a final diagnosis of ATN, and 106 (40%) patients had prerenal AKI. We excluded 36 (13%) patients with “other” causes of AKI. Using the final diagnosis as the gold standard, the ability of the preurine microscopy diagnosis to distinguish ATN from prerenal AKI was fair (sensitivity 0.76; specificity 0.86; positive LR 5.75). We calculated LR for both ATN and prerenal AKI from the results of microscopic examination (number of granular casts and RTEC) by final clinical diagnosis. These data are shown in Table 2. Using the LR calculated for either ATN or prerenal AKI, the posttest odds of either diagnosis can be estimated after multiplying the pretest odds by the LR from the urine sediment score (posttest odds = pretest odds × LR).

We evaluated the concordance of pre-urine microscopy diagnosis with final diagnosis. The diagnosis was changed in 23% of the patients with prerenal AKI (27 patients) to ATN and 14% of the patients with ATN (15 patients) to prerenal AKI (Table 3). Furthermore, we evaluated the role of urine microscopy on the change of diagnosis. We found that granular casts on urine microscopy were present in 85% of the patients whose diagnosis was changed from prerenal AKI to ATN (27 patients), and granular casts were not seen in 67% of the patients whose diagnosis was changed from ATN to prerenal AKI (15 patients; Table 4). In contrast, RTEC were not present in 60% of patients whose diagnosis changed from prerenal AKI to ATN.

*ATN, acute tubular necrosis; AKI, acute kidney injury; RTEC, renal tubular epithelial cells.
The urinary sediment scoring system was highly predictive of the final diagnosis of ATN. The odds ratio (OR) for ATN incrementally increased with an increase in severity of the scoring system (all compared with score 0; score 1: OR 9.7, 95% CI 5.3 to 18.6; score ≥2: OR 74.0, 95% CI 16.6 to 329.1; Tables 5 and 6). In patients with a high pretest probability of ATN (initial diagnosis of ATN), any granular casts or RTEC (score ≥2) resulted in very high PPV (100%) and low NPV (44%) for a final diagnosis of ATN. In patients with a low pretest probability of ATN (initial diagnosis of prerenal AKI), the lack of granular casts or RTEC on urinary sediment examination had a sensitivity of 0.73 and a specificity of 0.75 for a final diagnosis of ATN. The NPV of lack of granular casts or RTEC in patients with low pretest probability of disease was 91%.

### Discussion

In this study, we evaluated the urine sediment findings and scoring system based on granular casts and RTEC for differentiating ATN from prerenal AKI. Our study demonstrates that urine microscopy on the day of nephrology consultation is indeed a valuable diagnostic tool for strengthening the probability of a diagnosis of ATN. Furthermore, an ATN scoring system is useful for improving the differential diagnosis of ATN versus prerenal AKI.

It is generally accepted that urinalysis and urine microscopy with sediment examination are vital for the evaluation of patients with kidney disease, especially in differentiating the causes of AKI. This is particularly true for acute glomerulonephritis, acute interstitial nephritis, and pyelonephritis. Moreover, although urine sediment analysis is considered a part of the clinical workup of kidney disease in hospitalized patients with AKI, its true value in improving diagnosis is not clearly known (1–5). Furthermore, there has been a gradual trend away from using the simple, inexpensive, and rapid modality of urine microscopy in the evaluation of AKI. Unfortunately, it is not known whether this is an acceptable trend (urine microscopy adds nothing to the evaluation of AKI) or a negative trend (loss of useful information for the clinician evaluating the patient with AKI).

AKI is very common, especially in hospitalized patients, and it is strongly associated with increased mortality and morbidity (11–13). The most common cause of AKI in hospitalized patients is ATN followed by prerenal AKI (14). Hence, early differential diagnosis of AKI would assist in taking precautions to avoid further renal injury and potentially initiate early treatment to prevent kidney failure. Also, it would avoid worsening of the clinical course with incorrect therapies. For example, rapid-volume resuscitation in patients with prerenal AKI as a result of true volume depletion or judicious intravenous fluid use in patients with ATN would be appropriate management approaches guided by early diagnosis.

The hallmark of the ATN diagnosis is based on clinical history of the patient, physical examination findings, and lab-

*LR, likelihood ratio.
Conclusions

Urine microscopy and examination of the sediment has some advantages on the basis of widespread availability, technical simplicity with conventional equipment, and low cost. Our cross-sectional study of urine microscopy in the setting of hospital-acquired AKI suggests that ATN (sustained AKI) can be confidently differentiated from prerenal AKI. This was based on determining the presence of granular casts and using a scoring system based on the number of casts and RTEC. Further studies using other urinary indices such as fractional excretion of sodium and biomarkers (e.g., NGAL, IL-18, KIM-1) are warranted to elucidate better the role of granular casts, RTEC, and a scoring system in diagnosis and prognosis of ATN. In addition, the results generated from the ATN scoring system need to be replicated in a validation cohort.
